Abstract

There has been substantial interest, as of late, in the quantum-corrected form of the Bekenstein–Hawking black hole entropy. The consensus viewpoint is that the leading-order correction should be a logarithm of the horizon area; however, the value of the logarithmic prefactor remains a point of notable controversy. Very recently, Hod has employed statistical arguments that constrain this prefactor to be a non-negative integer. In the current paper, we invoke some independent considerations to argue that the “best guess” for the prefactor might simply be zero. Significantly, this value complies with the prior prediction and, moreover, seems suggestive of some fundamental symmetry.

I. MOTIVATION

It has long been accepted that black holes possess an intrinsic entropy which (for at least a wide class of models) can be determined by way of the famous Bekenstein–Hawking area law [1,2]; that is,

$$S_{BH} = \frac{A}{4} , \tag{1}$$

where S_{BH} is the entropy in question and A is the cross-sectional area (in Planck units) of the black hole horizon. Here and throughout, all fundamental constants are set equal to unity. Moreover, we will focus on the physically realistic case of only four uncompactified spacetime dimensions, as well as the case of a black hole that is neutral and static *modulo* quantum fluctuations (although many of our statements have more general applicability). Also, we will always assume the semi-classical regime of a macroscopically large black hole or $A \gg 1$. Further note that the above relation is, in spite of the implied presence of $\hbar$ (in the denominator), strictly a classical one.

Although the black hole area law initially followed from thermodynamic considerations (*e.g.*, protecting the second law of thermodynamics in the presence of a black hole [1]), it is

often presumed to have a statistical meaning as well [3]. Which is to say, one would naturally expect there to be a (yet-to-be-clarified) set of microscopic states that can account for this entropy by way of state-counting procedures. At this point, it is reasonable to suggest that such a statistical framework will ultimately be traced to some fundamental theory that is able to unify gravitational physics with quantum mechanics.

With cognizance of the above ideas, it becomes apparent that the Bekenstein–Hawking area law will provide an important viability test for any prospective theory of quantum gravity [4]. In fact, there has already been remarkable success in this direction: statistical calculations of the black hole entropy in the context of (for instance) loop quantum gravity [5], string theory [6], “Sakharov-style” induced gravity [7], near-horizon symmetries [8], *etcetera*. Perhaps, even too much success because, clearly, some further discrimination is still required. This realization has helped spark some recent interest into calculating the leading-order quantum correction to the classical quantity, S_{BH} [9].

In the remainder, we will elaborate on the nature of this correction and — with input from a variety of sources — make a novel deduction about what could be its precise value. We will end with a discussion on the possible implications (followed by an addendum).

II. QUANTUM-CORRECTED ENTROPY

Let us begin here by taking note of the typical outcome for the quantum-corrected entropy, S_{bh} , as obtained by a variety of methodologies: ¹

$$S_{bh} = S_{BH} + b \ln[S_{BH}] + \text{constant} + \mathcal{O}[A^{-1}] . \quad (2)$$

That is, the leading-order correction is, almost universally, found to be a logarithm of the horizon area. Unfortunately, there has been no such consensus with regard to the value of the logarithmic prefactor — denoted here by b . In fact, from a survey of the literature, the prefactor appears to be a highly model and method dependent parameter. On the other hand, as will be detailed later on, much of this ambiguity in b can be attributed to the following (often overlooked) point of relevance: There happens to be two distinct and separable sources to this logarithmic correction [11,12]. Nevertheless, even equipped with this knowledge, it has remained unclear as to how one might unambiguously fix this parameter. (A partially conjectural argument will, however, be presented in due course.)

Supposing that the value of b cannot be fixed, one might ask if there is any means for at least constraining this prefactor. As it so happens, this very question was recently addressed in a paper by Hod [13]. ² The premise of this work was to take seriously the statistical interpretation of the entropy in the context of Bekenstein’s notion of a quantum black hole area spectrum [15]. [The latter notion being that the horizon area, A , should be quantized according to

¹For a thorough list of references, see [10].

²The idea of constraining this parameter, but in the context of loop quantum gravity, has also been considered in [14].

$$A_n = \epsilon n , \quad (3)$$

where $n = 0, 1, 2, \dots$ and ϵ is a numerical factor of the order unity. (A_n might also include a constant term or zero-point area.) There has been substantial work in support of this form of spectrum [16]; most simply, it follows from the horizon area being an adiabatic invariant [17] along with Ehrenfest's principle.]

More precisely, “in the spirit of the Boltzmann–Einstein formula in statistical physics” [13], Hod suggested that the number of horizon microstates which correspond to a particular macrostate should be fixed equal to a positive integer.³ Given this line of reasoning, the degeneracy of the n th area eigenvalue (which translates into the exponential of the entropy) should be constrained as follows [13]:

$$g_n \equiv \exp[S_{bh}(n)] = \text{positive integer} , \quad (4)$$

for *any* allowed value of n . It should be noted that this constraining relation does not depend on what choice is made for the area spectrum [*i.e.*, at this point, A_n may or may not comply with equation (3).]

Hod then proceeded by writing the quantum-corrected entropy and area spectra in the most general forms that are consistent with the classical area law. More explicitly, A_n was written as an expansion in terms of n , and S_{bh} was expanded in terms of A ; where both expansions include a linear term, logarithmic term, a constant, as well as any number of sub-leading power-law terms (with the latter inclusion turning out to be irrelevant). To comply with the constraint equation (4), it was then shown that the entropy expansion must necessarily reduce to the form [13]

$$S_{bh} = S_{BH} + l \ln[S_{BH}] + \ln \left[\frac{(m+1)4^l}{\epsilon^l} \right] , \quad (5)$$

where ϵ is the coefficient of the linear term in the area expansion, and both l and m are non-negative integers.⁴ As a further point of interest, the area spectrum must reduce precisely to the form of equation (3) [except for the viable possibility of a $\ln(n)$ term, but only if $l = 0$ in equation (5)].

Comparing the above outcome with the quantum-corrected entropy of equation (2), we see that the logarithmic prefactor, or b , has now been constrained to be a non-negative integer. (Furthermore, the constant term has been somewhat constrained and the lower-order corrections can now be safely dropped.) The question we are now inclined to ask is how does such a condition on b comply with what is known (or can be deduced) from previous studies?

Before directly addressing this last query, let us first consider the possible sources for this logarithmic correction to the classical entropy. As alluded to above, there are two

³A similar point of view was used in Hod's earlier conjecture; which essentially identified the spacing of Bekenstein's area spectrum with the real part of the quasinormal mode frequency of a highly damped black hole [18].

⁴Here, we have slightly modified the notation of [13].

distinct contributing factors that need to be accounted for [11,12]. Firstly, there may be a quantum correction to the *microcanonical* entropy; that is, a fundamental correction to the number of microstates that are required to describe a black hole of fixed horizon area (and, consequently, fixed energy.) On intuitive grounds, a process of quantization should tend to remove uncertainty about the system, which would then typically translate into a decrease in the entropy. On the other hand, without a full understanding of the microcanonical degrees of freedom, it is impossible to say definitively that this would be the case. Nevertheless, if we assume that quantizing the black hole does reduce its entropy (an assumption that is supported by various calculations in the literature — see below), the microcanonical contribution to b will then be negative. (Recall that S_{BH} is always considered to be a very large number.)

Secondly, there may be quantum corrections that arise due to the black hole exchanging heat with its surroundings. (It is implicit that the black hole has been emersed in a thermal bath of radiation; precisely at the Hawking temperature. This is necessary for a state of thermal equilibrium to be reached; thereby fixing the *mean* or classical values of the energy and area.⁵) These thermal fluctuations in the horizon area are best interpreted as a *canonical* correction to the classical entropy. Inasmuch as thermal fluctuations increase the uncertainty of the system, any canonical contribution to b must certainly be positive. Hence, we have two conflicting contributions to the overall sign of b , and it is not *a priori* clear which will win out. Nonetheless, we will now proceed to argue (independently of the preceding analysis) that the resultant sum will indeed be a non-negative integer; in fact, it turns out to be zero.

Before proceeding on with the main discussion, let us point out that Hod’s paper [13] considers the quantum corrections at the most fundamental level; thus implying that the predictions therein refer strictly to the microcanonical corrections. So, under the premise of a comparison with [13], one might ask if it is fair to include canonical corrections in our calculation. We will argue here that the canonical corrections should indeed be included on the following basis: The entropy of a physical system is typically an observer-dependent concept, and this certainly applies to a black hole, inasmuch as a free-falling observer would detect no horizon (and, consequently, no associated entropy) whatsoever. This means that, if we are to assign an operational meaning to the entropy, a measurement must be performed or, equivalently, some sort of interaction with the black hole is required. From this point of view (*i.e.*, the black hole interacting with its surroundings), a canonical treatment would seem to be the appropriate one.

First of all, let us focus on the microcanonical correction. In principle, such a correction can only be properly quantified at the level of the (yet unknown) fundamental gravity theory. Nevertheless, certain calculations, especially in the conceptual framework of *loop quantum gravity* [9], have found a logarithmic correction of $-\frac{3}{2} \ln S_{BH}$; that is, $b_{mc} = -3/2$ (in hopefully obvious notation).⁶ Actually, this finding is not really as restrictive (in the

⁵More accurately, this state of affairs will fix the quantum-expectation values of these quantities, while still permitting quantum fluctuations.

⁶It is worth pointing out that this (loop quantum gravity) calculation does not seem to be tied to

sense of being tied to a specific model of quantum gravity) as it might appear to be. If the quantization of the horizon can be effectively described in terms of an “it from bit” (*ala* Wheeler [21]) model, then one will be able to reproduce the same result. To clarify somewhat, the horizon surface is segregated into patches of Planckian size, with each such patch represented by the simplest possible operator; namely, a single spin variable with spin equal to one half. Hence, any of the patches is to be labeled with either “spin up” or “spin down”.⁷ Given this picture, a series of straightforward calculations reveals that the entropy (defined as the logarithm of the number of states when the *sum* of the spins is zero) reproduces both the area law and the advertised logarithmic correction (*i.e.*, $b_{mc} = -3/2$) [23]. Even if this all feels rather *ad hoc*, the same basic calculation emerges quite naturally [11] out of the algebraic approach to black hole quantization [17].

When all is said and done, the most compelling argument for $b_{mc} = -3/2$ might be from a paper by Carlip [24]. An essential ingredient in this calculation was the leading-order correction to Cardy’s entropic formula [25]; notably, a formula that is applicable to a two-dimensional conformal field theory. Significantly, there is strong evidence that this type of field theory can effectively describe the horizon microstates of almost any stationary black hole [3,8].

We are now left with the daunting task of estimating the canonical contribution to the correction. In this regard, let us first turn to some relevant papers by Gour and the current author [26], and Chatterjee and Majumdar [27].⁸ In these treatments, the black hole is assumed (as noted above) to be in a state of thermal equilibrium with its surroundings; for descriptive purposes, one might envision a black hole enclosed in a “reflective box”. [Pragmatically speaking, one is able to mimic the scenario of a Schwarzschild black hole in a box by adopting the model of an anti-de Sitter (AdS) Schwarzschild black hole. This follows from the AdS spacetime having a confining potential that acts like a box of size L [30], where L is the AdS radius of curvature.] By virtue of this framework, the black hole system can now be effectively modeled as a canonical ensemble of particles and fields. The formal analysis [26,27] appropriately begins with a partition function of the following form:

$$\mathcal{Z}_C(\beta, L) = \sum_n g_n \exp[\beta E(n; L)] , \quad (6)$$

where β is the temperature of the heat bath, n and g_n are (as before) the quantum number and degeneracy for the area spectrum (with the latter, as usual, being identified with the exponent of the microcanonical entropy), E is the black hole energy or mass, and L is the box size or AdS radius when appropriate.

The calculation of the quantum-corrected entropy (*sans* microcanonical corrections) can then be accomplished in a number of steps. To briefly summarize:

any particular gauge group [19], which is a good thing in view of some recent controversies [20].

⁷The philosophical sector of the audience may wish to replace the spin variable with a *proposition* and replace up (down) with *true* (*false*) [22].

⁸For an earlier and a later example of related work, see [28] and [29].

- (i) the sum in equation (6) is re-expressed as an integral via the Poisson resummation formula,
- (ii) the integration variable is changed to E (taking into consideration a critical “Jacobian” factor),
- (iii) a saddle-point approximation is used to obtain a Gaussian integral that can readily be evaluated,
- (iv) standard thermodynamic relations are then utilized to extract the canonical entropy from the partition function.

Before proceeding any further, let us point out an important caveat: One finds that, in the next-to-last step, the formalism dramatically breaks down for any black hole with a negative specific heat. Perhaps disturbingly, this would be the case for even an “ordinary” Schwarzschild black hole. But, actually, this is not much of a surprise, given that a negative specific heat is a sure sign of thermodynamic instability. Moreover, it is not particularly worrisome, insofar as the specific heat will remain positive for an AdS–Schwarzschild black hole whenever L is (roughly speaking) no larger than the horizon size [31]. That is, the “size of the box” must be sufficiently limited for the notion of a thermally equilibrated black hole to make any sort of sense.

To finish off the outlined calculation, the authors of [27] assumed (along with the tree-level validity of the Bekenstein–Hawking entropy) that the energy has a simple power-law relation (of arbitrary power) with the area. [To be precise, this assumption translates into the requirement that $E \sim A^\eta$ is a valid leading-order expression for some choice of η . Certainly, this is not particularly restrictive, although there is a caveat which will be dealt with below.] Ultimately, they found a “universal” [27] logarithmic correction (due to canonical effects) of the form $+\frac{1}{2} \ln S_{BH}$; that is, $b_C = +1/2$.⁹

Although we have reiterated the claim of “universality”, this calculation is not quite as general as it may appear to be. Besides maintaining a positive specific heat, the black hole system is required (given the condition of thermal stability) to remain sufficiently far away from any phase-transition points [26,32]. Furthermore, it is in this very “grey area” that the assumed energy-area relation will become invalid (due to two or more evenly competing terms when E is expressed as a function of A). In Schwarzschild–AdS language, this translates into a lower bound on the horizon radius (or, alternatively, an upper limit on L) that is somewhat larger than the bound set by the point of the Hawking–Page phase transition or $A^{1/2} \sim L$ [31]. [Actually, the deviation between the two bounds goes as $L^{1/3}$ [32], which can be quite large in Planck units, but is rather small in relation to the size of a thermally stable black hole.] However, if such thermally unstable regions are indeed avoided, then any subleading terms in the energy-area relation must necessarily show up at lower than logarithmic order in the entropy. That is to say, given the validity of the canonical analysis, this outcome is exact and universal within the regime of interest.

As it now stands, the canonical correction would appear to be inadequate to (at the very least) cancel off the microcanonical correction; this being a minimal requirement for compatibility with the Hod prediction. However, the above cannot be the whole story, as

⁹Note that the exact same result was obtained in [26], although the model-specific focus of that paper shrouded the universality of the calculation.

we have not yet accounted for fluctuations in the black hole electrostatic charge and angular momentum. Which is to say, even if the black hole is, itself, neutral and static (by which we mean the equilibrium or classical values of the charge and spin are vanishing), the horizon area can still experience fluctuations due to a fluctuating charge or spin. It should be clear that such fluctuations cannot be suppressed for any realistic form of heat bath.

The pertinent question now becomes how might we quantitatively incorporate the charge and spin fluctuations into the canonical correction? Fortunately, for the case of a dynamical charge (we will momentarily neglect the issue of spin), this calculation has already been accomplished in [26]. The key point is that the formalism should now be appropriately generalized to that of a *grand-canonical* ensemble. More specifically, a suitably revised form for the partition function is expressible as follows [26]:

$$\mathcal{Z}_G(\beta, L) = \sum_m \sum_n g_{n,m} \exp[\beta E(n, m; L) - \mu Q(m)] , \quad (7)$$

where m is a “new” quantum number that quantifies the black hole charge ($Q = me$, where e is a fundamental charge unit) and μ is an electric (or, more generally, chemical) potential. After some well-motivated choices for the level degeneracy ($g_{n,m}$) and some lengthy calculations, it was shown [26] that this remodeled framework “typically” yields a logarithmic correction of $+1 \ln S_{BH}$; meaning that, once the charge fluctuations have been “turned on”, b_C increases from $+1/2$ to $+1$. Let us now clarify the range of validity or what is meant by the qualifier “typically”: This outcome of $b_C = +1$ will persist as long as we (once again) assume a positive specific heat and a sufficient separation from any phase-transition point,¹⁰ and (additionally) assume a small enough charge. In particular, the black hole cannot be too close to extremality, where *all* the fluctuations would be suppressed [26]. But note that, for the physically realistic case of a black hole that is at (or close to) a state of classical neutrality — as has assumed to be the case here — these are precisely the same conditions as discussed earlier.

Let us re-emphasize that, assuming the regime of thermal stability, the current analysis is independent of whether or not the black hole is classically neutral. For either eventuality, one can still anticipate large fluctuations in the charge on account of the continual ebb and flow of charged particles between the black hole and thermal bath. In fact, it has been shown that, even for a classically neutral black hole, the charge fluctuations go as $\Delta Q \sim \Delta A \sim S_{BH}^{1/2}$ [26].¹¹ It should also be pointed out that the calculation, as presented in [26], was somewhat model specific. Nevertheless, it is not difficult to extend this formalism to demonstrate that $b_C = +1$ is “universal” in our previously used sense. [To put it another way, this result persists for any (static) black hole with a positive specific heat, provided that the system is far from extremality and not too close to a phase-transition point. These conditions ensure both thermal stability and the leading-order validity of the critical relation $E \sim A^\eta$.]

¹⁰For the case of an AdS–Reissner–Nordstrom black hole — a natural generalization of the AdS–Schwarzschild model — there exists two such phase-transition points. One is the Hawking–Page analogue [31] and the other occurs when both the charge and the box are relatively large [33,32].

¹¹Given classical neutrality, the *relative* size of the charge fluctuations raises a interesting point. See Addendum 2 for further discussion.

Now, what about the fluctuations due to spin? Because of the complicated dynamics of a rotating spacetime and the vector nature of the angular momentum operator, such an analysis involves all sorts of technical difficulties. Nonetheless, we can still reasonably expect that each fluctuating degree of freedom will contribute $+1/2$ to the logarithmic prefactor (as follows from both the prior observations and the grand-canonical analysis of [34]). This argument leads immediately to a distinct possibility: Each of the three spin components (say, x , y and z) fluctuate independently, in which case the total contribution to the canonical correction prefactor is obviously $+3/2$. However, this is likely wrong, inasmuch as we are considering the implications of a quantized area spectrum. The relevant count should, in all likelihood, be that of the number of independent quantum numbers required to describe the spectrum. In the case of a fully general (four-dimensional) Kerr–Newman black hole, there are compelling reasons to believe that the number of such quantum numbers is precisely three; essentially, one for each of the mass, charge and spin sectors [35,36].¹² It then follows that the spin fluctuations, like the charge, will contribute an additional amount of $+1/2$ to canonical correction. Consequently, we arrive at $b_C = +3/2$ as our final (canonical) result. Note that the famous black hole “no-hair” principle [37] plays an essential role in restricting our considerations to just the three macroscopic contributors: mass, charge and spin. Even if there was some sort of “exotic (quantum) hair” to account for [38], it could certainly be dismissed as inconsequential in a semiclassical context.

Finally, summing the microcanonical and canonical contributions, we obtain an intriguing cancellation:¹³

$$b = b_{mc} + b_C = -\frac{3}{2} + \frac{3}{2} = 0 . \quad (8)$$

III. DISCUSSION

Our outcome of $b = 0$, although somewhat conjectural, does immediately satisfy a non-trivial consistency check; namely, it complies with Hod’s statistical constraint that the prefactor be a non-negative integer [13]. Moreover, if one interprets the well-known holographic principle [42] in its most literal form (so that $A/4$ is a strict upper bound on the black hole entropy), then a non-positive value of b would necessarily be favored [43]. This realization suggests that *zero* is, in fact, the *unique* choice of prefactor that is consistent with both the holographic principle and statistical mechanics.

¹²Alternatively, one might expect an equilibrated black hole system to have its axial asymmetries all smoothed out; thus, favoring one particular axis of rotation (say, z).

¹³The possibility of this type of cancellation has already been suggested in [39]; although on somewhat different grounds. There, it was pointed out that isolated-horizon boundary conditions [40] could reduce the (loop quantum gravity-based) microcanonical correction from $-3/2$ to $-1/2$ [41] (also see Addendum 1); thus canceling off the “universal” canonical correction of $+1/2$. However, contrary to the current presentation, this argument completely neglects the spin and charge fluctuations.

However, even if our arguments manage to hold up under closer scrutiny,¹⁴ there are (at least) a few open questions that should be addressed. First of all, do the lower-order corrections (*i.e.*, $\mathcal{O}[A^{-1}]$) vanish as also predicted by Hod and, perhaps more importantly, does the constant term comply with that of equation (5)? Conversely, for a macroscopically large black hole, it is not at all clear if it is sensible to talk about such small deviations (from a pure integer) in the level degeneracy [45]. Secondly, can we expect similar outcomes when the spacetime dimensionality differs from four? In this regard, it would seem reasonable to suggest that, for any viable number of spacetime dimensions, b will either be a half integer or full integer. However, only the latter outcome can be deemed as “acceptable” (and it would also have to be non-negative). At this point in the game, it is difficult to say anything more conclusive. Undoubtedly, it will be an instructive exercise to investigate some specific cases once the analytical “machinery” exists.

To end on a purely speculative note, it may be of interest if the value of b did turn out to be some preferred non-negative integer, irrespective of the model or number of dimensions. Since the canonical correction (a *quantum* effect) is a direct measure of the variety of (*classical*) black hole hair, such an eventuality could be viewed as a signal from the underlying theory of quantum gravity. (This type of idea — manifestations of quantum gravity in the macroscopic world — is similar in spirit to both the holographic principle [42] and the quasinormal mode conjecture of [18].) Our conjectured value of zero would promise even more intrigue; as such a precise cancellation seems suggestive of some fundamental symmetry being at play. Or, perhaps, Nature just abhors a logarithm.

ADDENDUM 1

Since the original version of this manuscript, there has been some dramatic developments in loop quantum gravity. More to the point, new calculations of the so-called Immirzi parameter [46] have just emerged [47,48]. As an immediate consequence, it would appear that the microcanonical contribution to the logarithmic prefactor is $-1/2$ (negating the older prediction, in loop quantum gravity, of $-3/2$). If this is indeed correct, then it follows that our net value for b should be adjusted from 0 to $+1$; in which case, Nature does *not* abhor a logarithm after all. Fortunately, this adjustment still complies with Hod’s constraint (*i.e.*, b should be a non-negative integer), so our main point remains intact. Also, it should be kept in mind that the precise status of these new calculations is still a matter of open debate [49,50].

ADDENDUM 2

Also since the original version of this manuscript, it has been suggested [51] that the grand-canonical analysis of [26] may be invalidated as follows: For a classically neutral or almost neutral black hole (our regime of interest), the *relative* charge fluctuation “blows

¹⁴It should be noted that there is at least one rigorous calculation of the quantum-corrected entropy for which no logarithmic term appears [44].

up" since $\Delta Q/Q \rightarrow \infty$ as $Q \rightarrow 0$. [Actually, the problem occurs because $\langle m \rangle \rightarrow 0$, since our partition function (7) is directly expressed in terms of the quantum numbers n and m .] It is then argued that this divergence would invalidate the small fluctuation (Gaussian) approximation, which was used to evaluate the partition function. We can, however, circumvent this criticism in the following way. As an alternative to the grand-canonical partition function (7) used previously, it is just as viable to write

$$\mathcal{Z}_G(\beta, L) = \sum_{m_-} \sum_{m_+} \sum_n g_{n, m_+, m_-} \exp[\beta E(n, m_+, m_-; L) - \mu Q(m_+, m_-)] , \quad (9)$$

where $Q = e(m_+ - m_-)$ with $m_{\pm} = 0, 1, 2, \dots$. That is, m_+ essentially represents the number of positively charge particles inside the black hole and m_- , the number of negatively charged particles. Now, if one proceeds to evaluate this new version of the partition function (see [26] for the details of the procedure), the result turns out to be identical to that obtained from equation (7) up to a constant factor. (Such a factor is, of course, irrelevant to calculations of the canonical entropy, *etcetera*.) The important point is that, for the semiclassical limit of a large black hole, $\langle m_+ \rangle$ and $\langle m_- \rangle$ are both finite (in fact, macroscopically large) irrespective of whether or not the black hole is, itself, classically neutral or charged. Hence, the Gaussian approximation will no longer break down in the suggested manner.

ACKNOWLEDGMENTS

The author would like to thank M. Visser for guidance, G. Gour for prior collaborations, and S. Hod and P. Majumdar for useful correspondences. Research is supported by the Marsden Fund (c/o the New Zealand Royal Society) and by the University Research Fund (c/o Victoria University).
